Multi-Agent Path Finding for Precedence-Constrained Goal Sequences

ABSTRACT

With the rising demand for deploying robot teams in autonomous warehouses and factories, the Multi-agent Path Finding (MAPF) problem has drawn more and more attention. The classical MAPF problem and most of its variants focus on navigating agent teams to goal locations while avoiding collisions. However, they do not take into account any precedence constraint that agents should respect when reaching their goal locations. Planning with precedence constraints is important for real-world multi-agent systems. For example, a mobile robot can only pick up a package at a station after it has been delivered by another robot. In this paper, we study the Multi-Agent Path Finding with Precedence Constraints (MAPF-PC) problem, in which agents need to visit sequences of goal locations while satisfying precedence constraints between the corresponding goals. We propose two algorithms to solve this problem systematically: Conflict-Based Search with Precedence Constraints (CBS-PC) is complete and optimal, and Priority-Based Search with Precedence Constraints (PBS-PC) is incomplete but more efficient in finding near-optimal solutions in practice. Our experimental results show that CBS-PC scales to dozens of agents and hundreds of goal locations and precedence constraints, and PBS-PC scales to hundreds of agents, around one thousand goal locations and hundreds of precedence constraints.

1 INTRODUCTION

As in the ongoing revolution towards building intelligent warehouse and factory systems, large teams of robots are expected to complete constantly dispatched tasks effectively. One typical example is the Kiva (now: Amazon Robotics) warehouse system, in which hundreds of Kiva robots are coordinated to transport movable shelving units, called inventory pods, on the fly without human intervention [17]. The Multi-Agent Path Finding (MAPF) problem is the problem of navigating a team of agents from their start locations to their goal locations while avoiding collisions. Due to the rising demand of developing such multi-robot systems, MAPF has drawn more and more attention, and MAPF algorithms are regarded as fundamental techniques to coordinating the motions of robot teams.

Although classical MAPF algorithms can find effective plans for navigating mobile robots in autonomous warehouses, they only plan for robots to reach single goal locations and thus cannot coordinate

Proc. of the 21st International Conference on Autonomous Agents and Multiagent Systems (AAMAS 2022), , , . © 2021 International Foundation for Autonomous Agents and Multiagent Systems (www.ifaamas.org). All rights reserved.

robots for fulfilling streams of tasks with precedence constraints over relatively long time horizons. For example, a mobile robot needs to move to several stations for delivering different packages, and another mobile robot can only pick up a package after it has been delivered to the corresponding station. The delivery and pickup tasks for robots can be modeled as sequences of goals for agents in MAPF, each goal specifies a goal location for an agent to visit. Since the tasks can be constrained by precedence requirements, goals between different agents can also be coupled in time. This can be modeled as a precedence constraint between the times of the two agents reaching their goal locations. Another example of precedence constraints is that materials can only be used in a manufacturing process after they have been delivered.

However, existing MAPF algorithms do not consider precedence constraints between goals when planning the path to reach a sequence of goal locations for each agent [5]. This motivates us to study the Multi-Agent Path Finding with Precedence Constraints (MAPF-PC) problem, in which agents need to complete sequences of goal (by reaching the goal locations) while satisfying precedence constraints between the goals. We present two algorithms for solving MAPF-PC: Conflict-Based Search with Precedence Constraints (CBS-PC) and Priority-Based Search with Precedence Constraints (PBS-PC), which generalize the state-of-the-art MAPF algorithms CBS [14] and PBS [10], respectively. We also propose several improvements to CBS-PC. Similar to CBS and PBS, CBS-PC is complete and optimal, and PBS-PC is incomplete but more efficient in obtaining near-optimal plans in practice.

We benchmark CBS-PC and PBS-PC on MAPF-PC instances with different numbers of agents, goal locations and precedence constraints. The results show that the most advanced CBS-PC variant scales to dozens of agents, hundreds of goal locations and precedence constraints, and PBS-PC scales to hundreds of agents, around one thousand goal locations and hundreds of precedence constraints.

2 PRELIMINARIES

In this section, we introduce Multi-Agent Path Finding (MAPF), Conflict-Based Search (CBS), prioritized planning, and Priority-Based Search (PBS) to provide the necessary background for the MAPF-PC problem and our MAPF-PC algorithms.

2.1 MAPF

The MAPF problem is defined by an undirected graph G = (V, E) and a set of m agents $\{a_1 \dots a_m\}$. Each agent a_i has a start vertex $s_i \in V$ and a goal vertex $g_i \in V$. In each timestep, an agent either moves to a neighboring vertex, waits at its current vertex, or terminates at its goal vertex (that is, it does not move anymore). Both move and wait actions have unit cost, and terminate actions have zero cost. A path of an agent is a sequence of actions that leads it from its start vertex to its goal vertex and ends with a terminate action. The path cost of a path is the accumulated cost of all actions in

this path. A *vertex conflict* happens when two agents stay at the same vertex simultaneously, and an *edge conflict* happens when two agents traverse the same edge in opposite directions simultaneously. A *solution* is a set of conflict-free paths of all the agents. A solution is an *optimal solution* if there are no other solutions with smaller objective values. Two common objectives for MAPF are the Sum of path Costs (SoC) and the makespan. The SoC is the sum of the path costs of the paths of all agents, and the *makespan* is the maximum path cost of the paths of all agents. Solving MAPF optimally is NP-hard for either objective [12, 18].

2.2 **CBS**

CBS [14] is a complete and optimal two-level MAPF algorithm. On the high level, CBS performs a best-first search on a Constraint Tree (CT). Each CT node contains (1) a set of constraints and (2) a set of paths, one for each agent, that satisfy all these constraints. The cost of a CT node is the SoC or makespan of all its paths, depending on the objective of the MAPF problem. CBS starts with the root CT node, which has an empty set of constraints and a path for each agent that has the smallest path cost when ignoring conflicts. When expanding a CT node, CBS returns the paths of it as a solution if the paths are conflict-free. Otherwise, CBS picks a conflict to resolve, splits the CT node into two child CT nodes, and adds a constraint to each child CT node to prohibit either one or the other of the two conflicting agents from using the conflicting vertex or edge at the conflicting timestep. CBS then calls its low level to replan the path of the newly constrained agent in each child CT node. On the low level, for a given CT node and a given agent, CBS finds a path for the agent that has the smallest path cost while satisfying all constraints of the CT node (but might conflict with the paths of the other agents in the CT node).

2.3 Prioritized Planning and PBS

Prioritized planning is a simple-yet-effective MAPF algorithm that orders the agents according to a predefined total priority ordering. A priority ordering \blacktriangleleft is a strict partial order on $\{a_1 \dots a_m\}$ where $a_i < a_j$ indicates that agent a_i is of higher priority than agent a_j . A total priority ordering \blacktriangleleft satisfies that, for any two agents a_i and a_j , we have either $a_i < a_j$ or $a_j < a_i$. Prioritized planning plans for agents in the order from highest priority to lowest priority. For each agent, it finds a path that has the smallest path cost while avoiding conflicts with the paths of all higher-priority agents. Whether prioritized planning finds a solution often depends on the predefined priority ordering, and it is not always easy to find a priority ordering that works.

PBS [10] is a two-level MAPF algorithm which systematically searches for such a priority ordering. On the high level, it performs a depth-first search on a *Priority Tree* (PT). Each PT node N contains (1) a *priority ordering* \prec_N and (2) a set of paths, one for each agent, that *respects* its priority ordering, i.e., the paths of any two agents a_i and a_j with $a_i \prec_N a_j$ are conflict-free. PBS starts with the root PT node, which has an empty priority ordering (that is, no agent is of higher priority than another) and thus a path for each agent that has

the smallest path cost when ignoring conflicts. When expanding a PT node, PBS picks a pair of conflicting agents, denoted as a_i and a_j , and splits the PT node into two child PT nodes, each extending the priority ordering of its parent PT node with either $a_i < a_j$ or $a_j < a_i$. PBS then calls its low level to replan the paths of the child nodes so that their paths respect their priority orderings. On the low level, for each PT node, PBS plans paths for agents in an order that is topologically sorted according to its priority ordering. Like prioritized planning, PBS plans a path for each agent that has the smallest path cost while avoiding conflicts with the paths of higher-priority agents. A PT node is pruned if PBS cannot find such a path for one of the agents. PBS returns a solution when it generates a PT node with conflict-free paths. PBS is neither optimal nor complete, but existing work shows that it finds solutions that are close to optimal and scales well to large numbers of agents [9, 10].

3 PROBLEM DEFINITION

The MAPF-PC problem is defined by an undirected graph G =(V, E), a set of m agents $\{a_1 \dots a_m\}$ and a set of precedence constraints \mathcal{T} . Each agent a_i has a start vertex $s_i \in V$ and a sequence of l_i goals $[g_i^1, g_i^2 \dots g_i^{l_i}]$. Each goal g_i^j corresponds to a goal vertex $g_i^j.loc \in V$. When agent a_i is at $g_i^j.loc$, it can (but is not required to) choose to *complete* goal g_i^j . Complete actions take zero timesteps and have zero cost. We use $\tau(q_i^j)$ to denote the completion timestep of g_i^j . Each precedence constraint $\langle g_i^j, g_{i'}^{j'} \rangle \in \mathcal{T}$ is a tuple of two goals g_i^j and $g_{i'}^{j'}$ and means that g_i^j must be completed before $g_{i'}^{j'}$. An agent must complete its goals in the order of the goal sequence one by one and terminate when it completes its last goal, and the completion timesteps of all the agents' goals must satisfy the precedence constraints as well. Besides vertex and edge conflicts, we consider a new type of conflicts called precedence conflicts. A precedence conflict happens when there exists a pair of goals g_i^j and $g_{i'}^{j'}$ such that $\tau(g_i^j) \geq \tau(g_{i'}^{j'})$ and $\langle g_i^j, g_{i'}^{j'} \rangle \in \mathcal{T}$. In MAPF-PC, a *path* for an agent also needs to specify the completion timestep of each goal of the agent. A path segment for goal g_i^J is a sequence of actions from the completion of g_i^{j-1} (or from timestep 0 if j = 1) to the completion of g_i^j . A solution to a MAPF-PC instance is a set of conflict-free paths for all agents.

The MAPF problem is a sub-class of the MAPF-PC problem where each agent has only one goal, and \mathcal{T} is empty. Therefore, solving MAPF-PC optimally is also NP-hard.

4 CBS WITH PRECEDENCE CONSTRAINTS

We introduce CBS-PC, a complete and optimal algorithm that solves the MAPF-PC problem. In this paper, we are interested in minimizing the SoC. However, CBS-PC can be made to work for other objectives such as minimizing the makespan or the sum of completion timesteps of goals by making small modifications to its low level. Similar to CBS, CBS-PC is a two-level MAPF algorithm that plans paths for single agents that visit multiple goal vertices on the low level and resolves vertex, edge and precedence conflicts on the high level.

¹The constraints in a CT are added by CBS to solve the MAPF problem. They are different from precedence constraints, which are part of the input of the MAPF-PC problem.

4.1 High Level of CBS-PC

On the high level, CBS-PC resolves vertex and edge conflicts in the same way as CBS. When CBS-PC picks a precedence conflict between goals g_i^j and $g_{i'}^{j'}$ that violates the precedence constraint $\langle g_i^j, g_{i'}^j \rangle$ (in other words, g_i^j needs to be completed before $g_{i'}^{j'}$ and this is not satisfied in the paths of the CT node). We use t to denote $\tau(g_i^j)$ as specified by the path of agent a_i . CBS-PC splits the CT node into two child CT nodes and resolves the precedence constraint by adding one of the following *completion timestep constraints* to one child CT node and the other one to the other child CT node:

- (1) $\tau(g_{i'}^{j'}) > t$: agent $a_{i'}$ must complete $g_{i'}^{j'}$ after timestep t. In the child CT node, the path of $a_{i'}$ is replanned, and $g_{i'}^{j'}$ is thus completed after g_i^j .
- (2) $\tau(g_{i'}^{j'}) \leq t$: agent $a_{i'}$ must complete $g_{i'}^{j'}$ no later than timestep t, which is already satisfied by the path of $a_{i'}$. However, due to precedence constraint $\langle g_i^j, g_{i'}^{j'} \rangle$, we have $\tau(g_i^j) \leq t-1$, which is not satisfied by the path of a_i . CBS-PC adds both constraints $\tau(g_{i'}^{j'}) \leq t$ and $\tau(g_i^j) \leq t-1$ to the child CT node, and the path of a_i is replanned.

When generating a child CT node with the completion timestep constraint in (1), the precedence conflict is immediately resolved since $a_{i'}$ is forced to complete $g_{i'}^{j'}$ after a_i completes g_i^j . When generating a child CT node with the completion timestep constraints in (2), CBS-PC tries to find a path for a_i that completes g_i^J earlier than t, which is the timestep when g_i^j is completed in the parent CT node. Such a path usually does not exist as t is often the smallest possible timestep when a_i can complete g_i^j , in which case CBS-PC prunes the child CT node. However, if such a path does exist, it is possible that the new path of agent a_i completes g_i^j still no earlier than $\tau(g_{i'}^{j'})$, in which case the two agents still have the precedence conflict. Nevertheless, $\tau(g_i^J)$ is guaranteed to decrease by at least one timestep. So, if CBS-PC continues to try to resolve the precedence conflict between the two agents, it will eventually either prune the branch that involves the repeatedly occurring precedence conflict or generate a child CT node where it is resolved.

One open question is which conflict to choose if the CT node to be expanded contains multiple conflicts. Existing work shows that choosing conflicts that increase the path cost in the child CT nodes can improve the scalability of CBS [1]. CBS-PC follows this principle and prefers precedence conflicts over vertex or edge conflicts (and breaks ties randomly) because the completion timestep constraint (1) often increases the path cost. We have also tried the conflict prioritization method in [1], but, unfortunately, this method turned out to be too computationally expensive for MAPF-PC instances since it needs to find all paths with the smallest path costs (known as MDD [15]) that complete all goals of each agent involved in each conflict.

4.2 Low Level of CBS-PC

On the low level, we need to plan a path for an agent that (1) completes all its goals, (2) satisfies the constraints imposed by the high level, and (3) minimizes the path cost. One might consider planning path segments for each goal sequentially instead of planning the

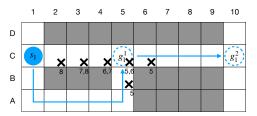

Figure 1: An example of low-level planning in CBS-PC. Agent a_1 has two goals g_1^1 and g_1^2 . Crosses represent vertex constraints on a_1 , and the numbers below them are the timesteps that a_1 is not allowed to stay at the vertices. For example, a_1 is not allowed to stay at C5 at timesteps 5 and 6.

entire path at once. The following example shows that planning sequentially can result in a sub-optimal path.

EXAMPLE 1. Figure 1 shows a case where agent a₁ has multiple vertex constraints, represented as crosses on the vertices and numbers that specify the constrained timesteps. If we plan path segments sequentially from one goal to the next, we first find a path segment to C5 at timestep 4 and then plan the path segment to C10. Because of the vertex constraints on B5, C5 and C6 at timestep 5, a₁ can move only to C4 at timestep 5. Then, at the next timestep, because of the vertex constraints on C4 and C5 at timestep 6, a₁ can move only to C3, and so on. Eventually, a₁ moves back to C1 at timestep 8, and thus can reach C10 at timestep 17 the earliest. However, if we plan the entire path of a₁ at once, a₁ can reach C10 already at timestep 13 when following the blue arrows.

To plan for the entire goal sequence, CBS-PC uses the Multi-Label A* algorithm (MLA*) [5, 9] to find a minimum-cost path that satisfies all constraints of the CT node. We extended MLA* to support goal timesteps constraints: (1) An agent can complete a goal only at a timestep that is larger than the lower bound on the completion timestep of the goal, if provided, , and (2) MLA* prunes any low-level search nodes in which the agent can reach a goal vertex only after the upper bound on the completion timestep of the goal, if provided.

4.3 Theoretical Analysis

CBS-PC differs from CBS in how the low level plans paths and how it addresses precedence conflicts. MLA* is complete and optimal []. Resolving precedence conflicts with completion timestep constraints does not rule out any solution of the MAPF-PC problem and, for every cost c, there is only a finite number of CT nodes with cost c in CBS-PC. With a proof similar to the one for CBS, we can therefore show that CBS-PC is complete and optimal.

4.4 Improvements

We now present three techniques for improving the efficiency of CBS-PC. One of them is a specialized technique for MAPF-PC, and the other two are adopted from existing work on improving CBS.

Constraint propagation: CBS-PC only adds completion timestep constraints when it picks a precedence conflict to split. However, additional completion timestep constraints can be inferred from the

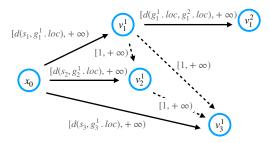

Figure 2: The STN for the root CT node of the MAPF-PC instance in Example 2.

existing ones in a way similar to how $\tau(g_i^j) \le t - 1$ is inferred in completion timestep constraint (2).

When generating a CT node, CBS-PC builds a *Simple Temporal Network* (STN) for the CT node [3]. An STN is a directed acyclic graph $\langle V, \mathcal{T}C \rangle$. Each vertex $v \in V$ represents a time point, called event, and $\tau(v)$ represents the occurrence time of v. Each STN has a reference event $x_0 \in V$ that represents the "beginning of time", and $\tau(x_0)$ is conventionally set to 0. Each edge $tc = \langle v, v' \rangle \in \mathcal{T}C$, annotated with the interval [LB, UB], indicates that v must occur between LB and UB time units after v', that is, $\tau(v') - \tau(v) \in [LB, UB]$. To construct the STN for a CT node, for each goal g_i^j , CBS-PC adds a vertex v_i^j to the STN to represent the completion of g_i^j . CBS-PC adds edges to the STN in three cases:

- (1) We use d(x,y) to denote the minimum cost needed to move from x to y in graph G. For each agent a_i , CBS-PC adds edge $\langle x_0, v_i^1 \rangle$ with interval $[d(s_i, g_i^1.loc), +\infty)$ to the STN, and, for each pair of consecutive goals g_i^j and g_i^{j+1} , CBS-PC adds edge $\langle v_i^j, v_i^{j+1} \rangle$ with interval $[d(g_i^j.loc, g_i^{j+1}.loc), +\infty)$ to the STN
- (2) For each precedence constraint $\langle g_i^j, g_{i'}^{j'} \rangle \in \mathcal{T}$, CBS-PC adds edge $\langle v_i^j, v_{i'}^{j'} \rangle$ with interval $[1, +\infty)$ to the STN.
- (3) For each completion timestep constraint $\tau(g_i^j) > t$, CBS-PC adds edge $\langle x_0, v_i^j \rangle$ with interval $[t+1, +\infty)$ to the STN. Similarly, for each completion timestep constraint $\tau(g_i^j) \leq t$, CBS-PC adds edge $\langle x_0, v_i^j \rangle$ with interval [0, t] to the STN.

The lower and upper bounds on the completion timestep of each goal in the STN can be computed using the Bellman-Ford algorithm. Each lower and upper bound can be converted to a completion timestep constraint. CBS-PC adds these constraints to the generated CT node if the CT node does not contain them already.

EXAMPLE 2. Consider a MAPF-PC instance with three agents. Agent a_1 has two goals, and agents a_2 and a_3 both have one goal. $\mathcal{T} = \{\langle g_1^1, g_2^1 \rangle, \langle g_1^1, g_3^1 \rangle, \langle g_2^1, g_3^1 \rangle\}$. Figure 2 shows the corresponding STN for the root CT node. The four solid edges are due to Case (1), and the three dashed edges are due to Case (2). We assume that $d(s_1, g_1^1, loc) > d(s_2, g_2^1, loc) > d(s_3, g_3^1, loc)$.

Figure 3a shows the CT of CBS-PC without constraint propagation. The text next to edges describes the constraints added to the CT nodes. Crossed-out CT nodes are pruned because CBS-PC cannot find paths for some agents. Without constraint propagation,

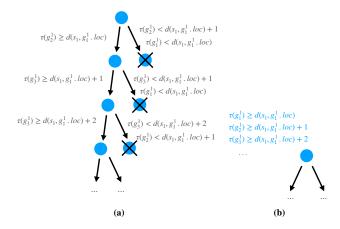

Figure 3: CTs of CBS-PC variants (with and without constraint propagation) when solving the MAPF-PC instance in Example 2.

CBS-PC needs to generate multiple CT nodes to resolve the precedence conflict because, in the root CT node, $\tau(g_3^1) < \tau(g_2^1) < \tau(g_1^1)$. Figure 3b shows the CT of CBS-PC with constraint propagation. The blue text next to the root CT node shows the constraints generated from constraint propagation, which impose lower bounds on the completion timesteps of goals. Since the low-level planner are aware of these goal timestep constraints, the root CT node does not contain the previously mentioned precedence conflicts.

Disjoint splitting: Different from the standard splitting rule of CBS, disjoint splitting [8] picks one conflicting agent, and then (1) adds a constraint to one child CT node to prohibit this agent from using the conflicting vertex or edge at the conflicting timestep and (2) adds a constraint to the other child CT node to force this agent to use the conflicting vertex or edge at the conflicting timestep, which implies that no other agent can use the conflicting vertex or edge at the conflicting timestep. Since disjoint splitting is able to speed up different variants of CBS significantly, we use it in the context of CBS-PC as well.

Target reasoning: A vertex conflict is a *target conflict* [7] if and only if one of the conflicting agents, denoted as a_i , terminates before the conflicting timestep, denoted as t. It is inefficient for CBS-PC to resolve target conflicts with only vertex and edge constraints. Instead, *target reasoning* [7] uses constraints $\tau(g_i^{l_i}) > t$ (the path of a_i needs to be replanned) and $\tau(g_i^{l_i}) \le t$ (the path of the other conflicting agent needs to be replanned because only a_i is allowed to occupy $g_i^{l_i}.loc$ at timestep t) to resolve target conflicts. Note that l_i denotes the number of goals of agent a_i .

5 PBS WITH PRECEDENCE CONSTRAINTS

We now introduce a suboptimal but more scalable MAPF-PC algorithm, called PBS-PC, which adopts the PBS algorithm for MAPF to solve our MAPF-PC problem. We start with a naïve version of PBS for MAPF-PC, which assigns priorities to agents to resolve conflicts.

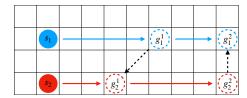

Figure 4: A two-agent MAPF-PC instance. Both agents have two goals. Solid-line arrows represent the sequence of vertices that agents need to visit, and dashed-line arrows represent the precedence constraints between goals.

We explain why naïve PBS might not work well and introduce an advanced variant called PBS-PC, which resolves conflicts by assigning priorities to goals.

5.1 Naïve PBS for MAPF-PC

Unlike CBS, PBS can be used to solve the MAPF-PC problem without any change on the high level. On the low level, when PBS plans for an agent, it uses MLA* to find a path that has the smallest cost while avoiding vertex, edge, and precedence conflicts with the paths of higher-priority agents. However, in MAPF-PC, planning for one agent after another is likely to fail because of the complicated precedence constraints.

EXAMPLE 3. Consider the two-agent MAPF-PC instance shown in Figure 4, where agents a1 and a2 have two goals each and $\mathcal{T} = \{\langle g_1^1, g_2^1 \rangle, \langle g_2^2, g_1^2 \rangle\}, \text{ that is, the first goal of } a_1 \text{ must be com-}$ pleted before the first goal of a2 and the second goal of a1 must be completed after the second goal of a_2 . In the root PT node, which has no priority ordering between a₁ and a₂, PBS plans for each agent individually. We have $\tau(g_1^1) = 5$ and $\tau(g_2^1) = 3$, which is a precedence conflict. PBS splits the root PT node into two child nodes. In one child node, it extends the priority ordering with $a_1 < a_2$, meaning that it plans the path of a_1 first. This path has $\tau(g_1^1) = 5$ and $\tau(g_1^2) = 8$. PBS cannot find a path for a_2 because it is impossible to satisfy $\tau(g_2^1) > 5$ and $\tau(g_2^2) < 8$ simultaneously. In the other child node, it extends the priority ordering with $a_2 < a_1$, meaning that it plans the path of a_2 first. This path has $\tau(g_2^1) = 3$ and $\tau(g_2^2) = 8$. PBS cannot find a path for a_1 because it is impossible to satisfy $\tau(q_1^1) < 3$. Thus, naïve PBS fails immediately for this simple MAPF-PC instance.

5.2 PBS-PC

In Example 3, PBS cannot solve the MAPF-PC instance because imposing priority orderings on agents is insufficient to resolve conflicts caused by complicated precedence constraints among goals. We thus propose PBS-PC, which assigns priority orderings to pairs of goals and plans the path segment for one goal at a time.

Algorithm 1 shows the high level of PBS-PC. We use Γ to denote the list of the goals of all agents. Unlike PBS, the root PT node of PBS-PC does not always have an empty priority ordering. PBS-PC initializes the priority ordering by (1) adding $g_i^j < g_i^{j+1}$ to $\blacktriangleleft_{Root}$ for each pair of consecutive goals of the same agent and (2) adding $g_i^j < g_{i'}^{j'}$ to $\blacktriangleleft_{Root}$ for each precedence constraint $\langle g_i^j, g_{i'}^{j'} \rangle \in \mathcal{T}$

Algorithm 1: High-Level Search of PBS-PC

```
1 ≺Root← ∅;
 2 foreach pair of consecutive goals g_i^j and g_i^{j+1} do
 3 \mid \blacktriangleleft_{Root} \leftarrow \blacktriangleleft_{Root} \cup \{g_i^j \prec g_i^{j+1}\};
 4 foreach \langle g_i^j g_{i'}^{j'} \rangle \in \mathcal{T} do
 5 \quad \bigsqcup \, \blacktriangleleft_{Root} \leftarrow \blacktriangleleft_{Root} \cup \{g_i^j \prec g_{i'}^{j'}\};
 6 Root.paths [q_i^j] \leftarrow empty for each goal q_i^j;
 7 STACK \leftarrow \{Root\};
 8 while STACK is not empty do
           N \leftarrow \text{STACK.pop()};
 10
           succ \leftarrow UpdatePath(N);
                                                                                 // Algorithm 2
           if succ is false then
11
                 continue;
 12
13
           if N.conflict is empty then
              return N.paths;
 14
           (g_i^j, g_{i'}^{j'}) \leftarrow N.conflict;
15
           foreach q \in (q_i^j, q_{i'}^{j'}) do
16
                 g' \leftarrow \text{the goal in } \{g_i^j, g_{i'}^{j'}\} \setminus \{g\};
17
 18

\prec_{N'} \leftarrow \prec_N \cup \{g \prec g'\};

 19
                 N'.conflict \leftarrow empty;
 20
                 \mathbf{foreach}\ g^{\prime\prime} \in (\{g^{\prime\prime}\mid g^\prime \prec_{N^\prime} g^{\prime\prime}\} \cup \{g^\prime\})\ \mathbf{do}
21
                      N'.paths[g''] \leftarrow empty;
                 Insert N' into STACK;
24 return "No Solution";
```

between the goals of two different agents. PBS-PC lazily begins with an empty path segment for each goal in the root PT node (Line 6 of Algorithm 1). When expanding a PT node, PBS-PC invokes Algorithm 2 to plan path segments (Line 10). Algorithm 2 plans for the goals in a topologically sorted order according to the priority ordering (Line 1) and plans for one goal at a time until:

- (1) PBS-PC cannot find a path segment for a goal (Lines 5 to 6), and the PT node is pruned on Lines 11 to 12 of Algorithm 1;
- (2) PBS-PC finds a conflict among non-empty path segments (Lines 9 to 11), and the PT node is split into two child PT nodes on Lines 15 to 23 of of Algorithm 1; or
- (3) the path segments for all goals are found (Line 12), and PBS-PC returns a solution for the MAPF-PC instance on Lines 13 to 14 of Algorithm 1.

When generating a child PT node, PBS-PC extends the priority ordering of the parent PT node with a new pair of goals. Let g' denote the goal of the lower priority in the new ordered pair. PBS-PC empties the path segments of g' and all paths that are of lower priority than it. PBS-PC returns "No Solution" if the stack is empty.

Algorithm 3 shows the algorithm for planning the path segment for goal g_i^j . If j=0, that is, g_i^j is the first goal of the agent, the start timestep and the start vertex of search are set to 0 and the start vertex of the agent, respectively. Otherwise, the start timestep and the start vertex are set to the completion timestep and the goal

Algorithm 2: UpdatePath(PT node N) 1 $TopologicalSort(\Gamma, \prec_N);$ 2 foreach $q \in \Gamma$ do if N.paths[q] is empty then 3 $p \leftarrow PlanPath(N, q);$ // Algorithm 3 4 if p is empty then 5 return false; 6 $N.paths[g] \leftarrow p;$ 7 $C \leftarrow FindConflicts(N, q);$ // Algorithm 4 **if** C is not *empty* **then** $N.conflict \leftarrow C$; 10

Algorithm 3: PlanPath(PT node N, goal g_i^j)

return true;

11

12 return true;

Algorithm 4: FindConflicts(PT node N, goal g_i^J)

```
1 foreach g \in \Gamma do
2 | if agent(g) is not a_i and N.paths[g] is not empty and
N.paths[g] \text{ has collisions with } N.paths[g_i^j] \text{ then}
3 | return (g, g_i^j);
4 return empty;
```

vertex of the immediate previous goal of the agent, respectively. The earliest timestep when a_i is allowed to complete g_i^j can be computed by checking the completion timesteps of all the goals that need to be completed before g_i^j (whose path segments are already planned because goals are planned in a topologically sorted order and the precedence constraints have been added to the priority orderings). Algorithm 4 shows the algorithm for conflict checking, which returns (1) a pair of goals whose planned path segments have vertex or edge conflicts; or (2) *empty* if no such q exists.

THEOREM 1. Solutions returned by PBS-PC are conflict-free.

(a) random-32-32-20

(b) warehouse-10-20-10-2-1

Figure 5: The grid maps of the MAPF-PC instances used in the experimental evaluation. $\,$

PROOF. In any PT node of PBS-PC, there is no precedence conflict between any two non-empty path segments because Algorithm 3 only finds path segments that satisfy all precedence constraints. The returned solution does not contain a vertex or edge conflict because, if there is one, the conflict will be found in Line 8 of Algorithm 2, and PBS-PC would not return the set of paths as a solution.

Similar to PBS, PBS-PC is not complete or optimal and the depth of the PT is $O(|\Gamma|^2)$ [10].

6 EXPERIMENTAL EVALUATION

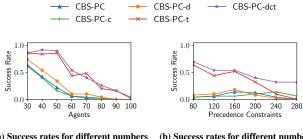

In this section, we compare the results of different variants of CBS-PC, PBS, and PBS-PC on MAPF-PC instances with four-neighbor grid maps. The variants of CBS-PC are CBS-PC, CBS-PC-c, CBS-PC-t, CBS-PC-d and CBS-PC-dct, where c adds constraint propagation, d adds disjoint splitting, and t adds target reasoning. All algorithms are implemented in C++² and share the same code base as much as possible. We ran all experiments on t2.large AWS EC2 instances with 8GB of memory. The time limit for solving each MAPF-PC instance was five minutes.

To generate a MAPF-PC instance, we randomly generated the start vertex of each agent and a set of goal vertices. Then, we began with an empty precedence constraint set \mathcal{T} , repeatedly picked a random precedence constraint and added it to \mathcal{T} if it is not in \mathcal{T} and will not introduce cycles until the number of precedence constraints reaches the given number. Then, we used the token passing algorithm [11] to greedily assign goals and generate the goal sequence for each agent.

We picked two grid maps from the MAPF benchmark [16]: random-32-32-20 and warehouse-10-20-10-2-1 (shown in Figure 5). For each grid map, we ran two sets of experiments: (1) MAPF-PC instances with different numbers of agents (ranging from 30 to 100), 200 goals, and 120 precedence constraints. (2) MAPF-PC instances with different numbers of precedence constraints (ranging from 80 to 280), 200 goals, and 60 agents. For each number of agents or precedence constraints, we generated 50 random instances.

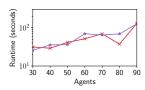

Comparing variants of CBS-PC: Figures 6 and 7 show the results for the CBS-PC variants. The *success rate* of an algorithm is the percentage of MAPF-PC instances that it solves within the time limit. For the CBS-PC variants without target reasoning, CBS-PC-d almost always had slightly higher success rates than CBS-PC. CBS-PC-c had similar or slightly worse success rates than the other two variants when the number of precedence constraints was less than 200 because the computational overhead outweighs the benefit

²Our code and data will be publicly available upon publication of the paper.

of the technique. However, it had better success rates than the other two variants when the number of precedence constraints was large enough (namely, ≥ 240) because constraint propagation significantly reduced the number of precedence conflicts that need to be resolved.

The CBS-PC variants with target reasoning, CBS-PC-t, and CBS-PC-dct have better success rate than the other three variants in most of the experiments. CBS-PC-dct had better success rates than CBS-PC-t when the number of precedence constraints is large but similar success rates otherwise. We show the runtimes of CBS-PC-dct and CBS-PC-t averaged over all instances solved by both of them. The runtime results align with the success rate results, CBS-PC-dct and

CBS-PC-t had similar average runtime except in some instances with a large number of precedence constraints, where CBS-PC-dct solved the instances much faster. We omit the runtime results of the other three variants because they solved too few instances within the time limit.

Comparing PBS and PBS-PC: Figures 8 and 9 show the results for PBS and PBS-PC. In general, PBS-PC outperformed PBS in terms of both the success rate and the runtime. The success rates of PBS stayed similar or even increased when the number of agents increased. However, the success rates of PBS quickly dropped as the number of precedence constraints increased, which shows that PBS was not good at solving MAPF-PC instances with complicated precedence constraints.

Comparing CBS-PC and PBS-PC: In general, PBS-PC outperformed all CBS-PC variants in terms of both success rate and runtime. In Figures 8e, 8f, 9e, and 9f, we show the suboptimality results for PBS-PC. The dots show the suboptimality ratios of PBS-PC on MAPF-PC instances that were solved by some variant of CBS-PC and the lines show the average suboptimality ratios. The suboptimality ratios of PBS-PC were on average less than 1.1 in most cases and around 1.2 in the worst case. The average suboptimality ratios of PBS-PC increased as the number of agents increased because PBS-PC is more likely to add priority ordering due to the increasing number of vertex and edge conflicts, which increase its suboptimality. Interestingly, the average suboptimality ratios of PBS-PC decreased as the number of precedence constraints increased. It was because agents were less likely to have vertex or edge conflicts when they need to wait longer due to the increasing number of precedence constraints.

Scalability of PBS-PC: We ran two additional experiments for only PBS-PC on warehouse-10-20-10-2-1 to see how PBS-PC scales on difficult instances: (1) MAPF-PC instances with different numbers of agents m (ranging from 100 to 500), where the numbers of goals were 2m and the numbers of precedence constraints were m, and (2) MAPF-PC instances with different numbers of goals n (ranging from 800 to 1800), the numbers of precedence constraints were 0.5 * n and the numbers of agents were always 200. Figure 10 shows the results. PBS-PC solved all instances with up to 300 agents in experiment (1) and all instances with 800 goals in experiment (2).

7 RELATED WORK

Numerous algorithms have been developed to solve multi-task multi-agent path finding problems by assigning tasks (in form of goal locations) to agents with the purpose of minimizing the execution time. One representative approach is to formulate the problem as Vehicle Routing Problem with Time Windows (VRPTW) and minimize the execution time over the entire time horizon [2, 6]. A survey of task-assignment algorithms can be found in [4]. However, most of these algorithms ignore inter-agent collisions and thus cannot be directly executed in safety-critical scenarios. Moreover, as our MAPF-PC algorithms are capable of planning with goal vertex sequences and precedence constraints, they can be used in conjunction with most of the aforementioned task-assignment algorithms to generate collision-free paths with respect to the assigned goal vertex sequences.

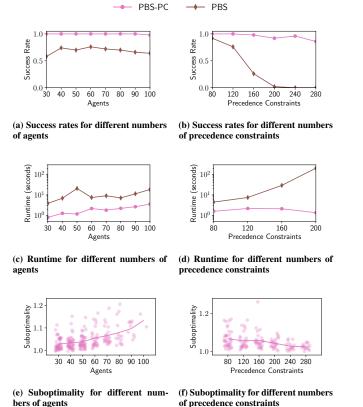

Figure 8: Results of PBS-PC and PBS for random-32-32-20.

Among all algorithms that aim at planning collision-free paths for streams of tasks, the algorithms in [2, 13] are able to handle precedence constraints between tasks and thus are most related to ours. [2] presents a four-level algorithm that is able to solve the general Precedence-Constrained multi-agent Task Assignment and Path-Finding (PC-TAPF) problem, although it is demonstrated only on assembly scenarios. Its first level iteratively searches for promising task assignments, and the other three levels plan collisionfree paths based on the task assignment. As the latter solves the same problem as MAPF-PC, It is neither complete nor optimal since it plans each path segment in a myopic way, which does not consider the feasibility or optimality of achieving the following tasks. In comparison, our CBS-PC algorithm generates provably optimal plans. While both the algorithm in [2] and PBS-PC are suboptimal, PBS-PC is able to plan for 300 agents with 800 goals while the algorithm in [2] can merely plan for 40 agents with 60 tasks in the same runtime. Our CBS-PC algorithm can be integrated with its task assignment module (i.e., first-level solver) to create an optimal PC-TAPF algorithm.

[13] also presents a complete algorithm for solving multi-task multi-robot path finding problem with precedence constraints. However, this algorithm relies on the assumption that each task can only have one precedence constraint, which prevents the algorithm from solving realistic scenarios with complex precedence constraints. For

example, modeling that some packages that need to be delivered to their goal locations first can introduce multiple precedence constraints.

8 CONCLUSIONS AND FUTURE WORK

In this paper, we proposed the MAPF-PC algorithms CBS-PC and PBS-PC. CBS-PC is complete and optimal, and we proposed several improvements for it. PBS-PC is incomplete and suboptimal but efficient in practice. We evaluated these algorithms on MAPF-PC instances with different parameters, and the results showed that the most advanced CBS-PC variants scale to dozens of agents and

hundreds of goals and precedence constraints and PBS-PC scales to hundreds of agents, around one thousand goals and hundreds of precedence constraints.

An interesting direction for future work is to extend the MAPF-PC problem with other types of inter-goal constraints, such as simple temporal constraints between the completion timesteps of goals. Another direction is to study different types of MAPF-PC algorithms, such as bounded sub-optimal or anytime algorithms.
